Europhysics Letter was launched more than fifteen years ago by the European Physical Society, the Société Française de Physique, the Società Italiana di Fisica and the Institute of Physics (UK) and owned now by 17 National Physical Societies/Institutes.

Europhysics Letters aims to publish short papers containing non-trivial new results, ideas, concepts, experimental methods, theoretical treatments, etc. which are of broad interest and importance to one or several sections of the physics community.

Europhysics letters provides a platform for scientists from all over the world to offer their results to an international readership.

PACS. 87.15. -v -Biomolecules: structure and physical properties.

Abstract. -We present a new method to study the melting transition of DNA oligonucleotides, which can quantify the presence of intermediate states. The approach is to combine UV spectroscopy with a method based on trapping intermediate states by quenching. The measurements yield both the average fraction of open base pairs (f) and the fraction of completely open molecules (p). If intermediate (partially open) states are not present, then $p = f$ throughout the transition. In the presence of intermediate states, $p < f$. We demonstrate the method on the example of a 48mer sequence which is designed to open at one end and thus have intermediate states during melting. Then we show a different sequence design where the melting appears essentially as a two-states process. These experiments demonstrate the role played by end effects and sequence design in controlling the nature of the melting transition for DNA oligomers.

Introduction At sufficiently high temperatures, the DNA double helix melts and the molecule separates into two single strands. While this transition has been studied extensively, the question of what conformations are statistically significant during melting is not clear. Long DNA molecules give rise to steps in the melting curves [14], corresponding to different regions of the molecule melting at different temperatures. For synthetic oligonucleotides with uniform sequences this behavior is not observed [12].

In molecular biology, thermal denaturation is exploited with the polymerase chain reaction (PCR). For quantitative PCR [7-10], an understanding of the sequence specificity of the hybridization and melting processes is desirable.

For short oligomers (< 10 bp) an adequate representation of the melting transition is obtained from a two-states model in which the molecules are either completely closed or completely open. For long molecules, a better description is obtained from the "zipper model" [11], which allows partially open (intermediate) states. Two main approaches have been studied: Ising-type models, which assign an energy difference for paired and unpaired bases [12-17], and models which introduce a potential energy function of the distance between the bases [18-22]. Depending on the details of the treatment of the entropy of single-stranded loops, these models predict a continuous [14-16,19] or discontinuous [17,18,21,22] transition in the thermodynamic limit.

Experimentally, several techniques are employed to characterize the transition [11], including UV absorption, circular dichroism (CD), fluorescence spectroscopy, and calorimetry. The thermodynamic parameters have been measured by spectroscopic [23] or calorimetric [24] methods, or a combination [25,26]. Fluorescence energy transfer has been used to measure free-energy differences through competitive binding assays [27], and to probe the dynamics of hairpin formation [28]. Temperature gradient gel electrophoresis (TGGE) can detect conformational transitions and mismatches [29-32].

Melting is usually monitored by the UV absorption near 260 nm; this absorption increases typically by 40% going from double strand to single strand, due to the fact that the corresponding electronic transitions within the bases are partially screened when the bases are stacked. In the context of melting studies, these spectroscopic measurements are interpreted as yielding the average fraction of open base pairs, which we call f .

A limitation common to all spectroscopic methods, which average over the whole molecule population, is that one cannot distinguish between different configurations. For example, at a temperature where the UV absorption indicates that half the base pairs are open, the measurement does not distinguish a situation in which half the molecules are completely open and half are completely closed, from a situation in which all molecules are half-way open. One does not have direct access to intermediate states.

Here we introduce a new method to trap intermediate (partially open) states. The principle is to use partially self-complementary sequences, so that the single strands can form hairpins (hp). A sample initially in the duplex state (*i.e.* hybridized to its reverse complement) is taken to a given temperature T within the transition range, then quenched to lower temperature. Strands which were completely separated at the temperature T are trapped in the hairpin conformation after quenching, and the fraction of hairpins can be determined by gel electrophoresis. This method was used in the laboratory of Deborah Fygenon [33] to study how DNA-binding dyes affect the melting temperature. Our approach here is to combine spectroscopic measurements with this quenching technique in order to measure both the fraction of open base pairs and the fraction of completely open molecules. This allows us to quantify the presence of intermediate states.

First, we demonstrate the method on a 48mer sequence (L48AS) designed to open at one end; we find that for this sequence, at the midpoint of the transition all molecules are in intermediate, partially open states. Then we present the case of a 42mer sequence of different design, where the transition turns out to be essentially a two-states process. Thus we show that for the finite-size system, the nature of the transition is controlled by end effects and therefore sequence design.

Experimental technique. - Sample preparation. Synthetic DNA oligonucleotides were purchased from Operon Technologies, HPLC purified. The two sequences used in this study (fig. 1) are partially self-complementary, thus the ss can form hairpins as indicated in the figure. However, the ground state is the duplex (ss + reverse complement, not shown in the figure). In the duplex form, L48AS has a G-C-rich (*i.e.* more stable) region at one end, and an A-T-rich region at the other. L42VI has G-C-rich regions at both ends and an A-T-rich region in the middle.

For the experiments, the initial state was prepared in the duplex form by annealing each oligomer with its reverse complement, at an oligomer concentration of 50 μ M, in PBS diluted by 3 (3 mM phosphate buffer, 1mM KCl, 46 mM NaCl). Samples were brought to 90 °C and cooled overnight, then diluted in the same buffer to reach the desired oligomer concentration for the experiments, which was 1 μ M both for the quenching and the UV measurements.

UV absorption measurements were performed at 260 nm with a Beckman Coulter DU-640

Fig. 1 - Synopsis of the quenching method wed to trap intermediate states. Completely open molecules can be sorted from partially open ones because the former form hairpins upon quenching to lower temperature. The lower part of the figure shows the two sequences used in this study, and the hairpins they can form.

spectrophotometer equipped with temperature-controlled sample holder. The temperature ramping rate was $0.5^\circ/\text{min}$. CD measurements were performed on a Jasco spectrometer at 248 nm.

Quenching technique. To measure the fraction of completely open molecules we developed the following technique. A number of aliquots (i) of the same sample are heated to different temperatures T_i within the transition range and then quenched to $\sim 0^\circ\text{C}$. Molecules which were completely open at the temperature T_i (i.e. single strands, ss) form hairpins after quenching, while molecules which were partially open close again as duplexes (fig. 1). This occurs because under the dilute conditions of the experiment it is faster for single strands to form hairpins upon quenching. Subsequently, the aliquots are run on a gel, and the relative amount of hairpins and duplex molecules is determined from the intensities of the two bands. The relative amount of hairpins represents the equilibrium fraction of completely open molecules at temperature T_i . Note that this is an equilibrium, not a kinetic measurement.

Trapping the single strands in the hairpin conformation lowers the rate $ss \rightarrow ds$ recombination, which makes the experiment practical. The key observation is that a sample which is not heated produces a ds band (and no hp band) in the gel (fig. 2a, bottom lane), while a sample which was heated at sufficiently high temperature and quenched shows up entirely as a hp band in the gel (fig. 2a, top lane). This shows that the interconversion $hp \leftrightarrow ds$ after quenching is slow enough that the experiment is viable, and that the electrophoresis process does not transform hairpins into duplexes or vice versa. Thus the method may be better suited for melting studies than TGGE.

In practice, $30 \mu\text{l}$ aliquots (DNA concentration $1 \mu\text{M}$) in PCR tubes were brought to the desired temperature in a water bath for 3 min, then quenched to 0°C by plunging the tubes in ice water. Gel electrophoresis (typically 80min at 100V) was run in a chilled mini-sub

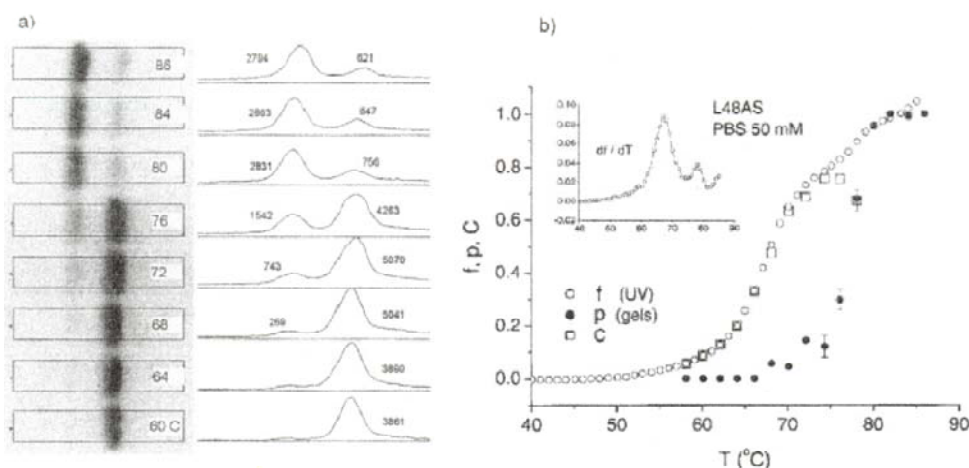

Fig. 2 - Melting transition for the 48mer L48AS in PBS 50mM. a) Gel electrophoresis of aliquots which were heated to the temperatures indicated on the lanes and quenched to 0 °C. The gel runs right to left. There are only two species present: duplexes (slow band) and hairpins (fast band). Next to the lanes we plot the intensity profiles; the numbers are proportional to the areas under the peaks. b) The fraction of open base pairs f (open circles; obtained from the UV absorption measurements), the fraction of open molecules p (filled circles; obtained from the gels), and the quantity C (squares; calculated from eq. (3)), which represents the mean bubble length. The inset shows the derivative of the UV data: two peaks are visible, corresponding to the two steps in the UV curve.

cell (BioRad) under TE buffer with ethidium bromide, using 3% agarose gels (LMP from Promega). Gels were photographed under UV illumination with a digital camera (Fuji FinePix 4900), and the intensities of the bands read out using the image analysis program Scion Image. The same bands are obtained if the gels are stained at the end.

Data analysis From the UV absorption measurements we obtain the average fraction of open base pairs, f . From the quenching technique, we obtain the average fraction of open molecules, p . The relationship between these quantities yields a characterization of the transition. If bubbles are present at a given temperature, then at that temperature $p < f$. In the case that the molecules unzip gradually, in the transition region ($0 < f < 1$) there will be mostly partially open molecules, *i.e.* $p \approx 0$. In the opposite extreme case of a two-states transition, $p = f$ throughout.

1) *Normalization of the spectroscopic measurements.* Calling A_{\min} and A_{\max} the minimum and maximum values of the absorption (or CD signal) within the transition region, we calculate the fraction of open base pairs f as

$$f(T) = (A(T) - A_{\min}) / (A_{\max} - A_{\min}),$$

where $A(T)$ is the absorption (CD signal) at temperature T . All UV and CD curves show clear plateaus at temperatures well below the transition; the corresponding values determine A_{\min} . A_{\max} is easily determined in the case of L42V1, because the CD curve has a plateau for $76 \text{ °C} < T < 85 \text{ °C}$ (fig. 3). In the case of L48AS (fig. 2b), one can discern in the UV curve two steps, which given the sequence of L48AS, must be tentatively assigned to the melting of

Fig. 3 - Melting transition for the 42mer L42V1 in PBS 50 mM. The fraction of open bp obtained both from the CD (open circles) and UV measurements (triangles) is shown, together with the fraction of open molecules p (filled circles). The dashed line is a fit of the CD curve with the two-states model [11]: $f = \exp[s - \epsilon/T] / (1 + \exp[s - \epsilon/T])$, where ϵ and s are energy and entropy parameters (the melting temperature is then $T_m = \epsilon/s$, at which point $f = 1/2$). The parameters of the fit were $T_m = 343.0\text{K}$, $\epsilon = 3.83 \times 10^4\text{K}$.

first the A-T-rich region and then the G-C-rich region. We normalized the UV curve so that $f = 1$ after the second step. This also produces a melting curve which is consistent with the gel data, since the two curves then cross at $f = 1$, $p = 1$ ($T \approx 81^\circ\text{C}$).

Normalization of the gel measurements. There are several ways of calculating the hairpin fraction from the band intensities in the gels. Calling $hp(T)$ the intensity of the hairpin band of the aliquot which was brought to temperature T , and $ds(T)$ the intensity of the duplex band, we used the following normalization for the hairpin fraction p :

$$p(T) = hp(T) / (hp(T) + ds(T)). \quad (1)$$

This quantity compares hp and ds intensities within the same lane, and is independent of the amount of sample in the lanes. Alternatively, we can compare bands across lanes, and obtain a normalization which is independent of the efficiency of dye binding to the two structures, hairpin and duplex. The two normalizations give rise to the same melting curves.

Results. - Figure 2a shows the gel for L48AS. The temperatures to which the samples were heated before quenching are indicated on the lanes. The initial state is prepared in the duplex form. At the highest temperature (86 °C) the sample has turned almost entirely into hairpins. The plots on the right show the intensity integrated across the lane; the areas under the peaks were used to obtain the melting curves shown in the next figures.

The melting curves are shown in fig. 2b. Here and in the next figure, errors were estimated from the reproducibility of the data and analysis; they are of order 3% for the UV data and 10% for the gel data. The data clearly reveal the presence of intermediate states, since $p < f$ throughout the transition. At a temperature such that $f = 0.5$ ($T \approx 68^\circ\text{C}$), essentially no molecules are completely open ($p \approx 0$), i.e. all molecules are in intermediate (partially open) states. We can quantify the average conformation of these intermediate states by introducing a quantity C which is the average fraction of open base pairs within the partially open molecules

(this is the average size of the bubble for the partially open molecules). The total fraction of open base pairs can be written as

$$f(T) = (1 - p(T))C(T) + p(T), \quad (2)$$

where the first term is the fraction of partially open molecules multiplied by the fraction of open *bp* within this subset, and the second term is the fraction of completely open molecules. Therefore

$$C = (f - P)/(1 - P). \quad (3)$$

Note that close to the endpoint of the transition, $p \approx 1$ and from (3) the error bars for C will be large. The quantity C , calculated from f and p using eq. (3), is plotted in fig. 2b as open squares. We see that the average size C of the single-stranded region accounts for the whole fraction of open base pairs ($C = f$) till the first kink in the UV curve ($T \approx 70^\circ\text{C}$). Beyond that temperature C seems to reach a plateau. This suggests the following picture of the transition: the A-T-rich region at one end unzips gradually with increasing temperature, until a temperature is reached where the G-C-rich region starts to melt ($T \approx 70^\circ\text{C}$), this latter process happening abruptly. In summary, the behavior of the quantity C suggests a continuous transition for the A-T-rich region, and a discontinuous one for the G-C-rich region.

In fig. 3 we show the melting curves for L42V1. Apart from being slightly shorter, this sequence is different from L48AS: in the duplex form it has G-C-rich regions at the two ends, and an A-T-rich region in the middle. The melting behavior is completely different from that observed for L48AS: essentially, no intermediate partially open states are detected ($p = f$ throughout), *i.e.* within the resolution of the method, the transition appears as a two-states process. This is not apparent from the f curve or the p curve alone, which are continuous (the transition region has a finite width) because of finite-size effects.

Discussion We have introduced a new method to study intermediate states in the melting transition of DNA oligonucleotides. By combining a spectroscopic technique (UV absorption) with a simple method based on quenched states we measure both the average fraction of open base pairs f and the fraction of completely open molecules p . From the relation between these two quantities we quantify the presence of intermediate states. We find that a sequence designed to open at one end indeed shows such equilibrium intermediate states. However, a second sequence which could be expected to develop a denaturation bubble in the middle instead melts in a two-states process. This demonstrates that end effects, and therefore sequence design, can control the nature of the transition in the case of oligomers.

The method presented here offers a clear-cut criterion for recognizing a first-order transition behavior ($f = p$). In the case of oligomers, this is not obvious from the UV absorption curves alone, which always look continuous because of finite-size effects. Furthermore, the abrupt melting of stable regions can be detected by plateaus in C . We believe the method can systematically address the role of end effects, oligomer length, and sequence in shaping the character of the melting transition.
